Edward Amankwah

EXECUTIVE SUMMARY

Medical Data Processing Company, a San Francisco-based Electronic Medical Record (EMR) analytics provider founded in 2007, serves over 8,000 medical facilities across the United States — including hospitals, urgent care clinics, emergency rooms, nursing homes, and critical care units. Its customers rely on the platform to maintain HIPAA regulatory compliance, track patient health metrics, monitor bed availability, and manage admit/discharge records in real time. With approximately 1,100 customers and 370 employees, the company occupies a critical position in the healthcare data infrastructure landscape.

The company's growth has significantly outpaced its technical infrastructure. Since its founding, operations have been built on a monolithic three-tier architecture backed by a single-node Microsoft SQL Server instance — a system that was appropriate for early-stage workloads but is fundamentally incapable of supporting the scale, velocity, and analytical demands of the company today. The database now holds over 8 TB of data at 70% capacity, processes an average of 15 million data files daily from facilities transmitting CSV, XML, and TXT records via FTP servers and REST APIs, and is growing at 15–20% annually. Last week, a surge in nightly ETL data volumes caused a complete SQL Server crash that took the entire platform offline for several hours, disrupting services to all 8,000 facilities — a direct patient safety and regulatory risk.

This report presents a comprehensive analysis of the problem, the dataset characteristics, and a fully designed open-source Data Lake solution that directly addresses every identified failure. The proposed architecture replaces the monolithic SQL Server with a four-layer Hadoop-based Data Lake: an Ingestion Layer (Apache NiFi, Kafka, Debezium), a Storage Layer (HDFS with a medallion zone structure and Apache Hudi for CDC), a Processing Layer (Apache Spark, Kafka Streams, Flink, Hive, Impala, Presto), and a Serving Layer (Apache Superset, MLflow, REST APIs). The entire stack is open-source, HIPAA-compliant, horizontally scalable, and fault-tolerant — eliminating vendor lock-in while reducing storage costs by 40–60% through intelligent hot/warm/cold tiering.

The business value of this transformation extends beyond technical stabilisation. The proposed Data Lake enables near-real-time analytics, machine learning on live data without data movement, and a single governed source of truth that eliminates the data silos, duplication, and version sprawl that currently cripple the company's analytical capabilities. Replacing 70+ fragile SSIS ETL scripts with a single metadata-driven PySpark framework radically reduces operational overhead and accelerates onboarding of new facility data sources. This report is intended to

provide the CTO and leadership team with the technical depth, strategic rationale, and evidence base needed to approve and fund the Data Lake modernisation initiative.

1. PROBLEM STATEMENT

Medical Data Processing Company faces an existential infrastructure crisis driven by the collision of hypergrowth and technical debt. Its legacy architecture — a monolithic three-tier system anchored by a single-node Microsoft SQL Server — was never engineered to handle the data volumes, velocity, or analytical complexity the business now demands. The system processes data from 8,000 facilities producing an average of 77,000 compressed zip files per day (3,500 per hour at peak), each containing CSV, TXT, or XML records. The SQL Server at the core of this pipeline now holds 8 TB of data on a 12 TB disk already running at 70% capacity. At the current 15–20% annual growth rate, the disk will reach saturation within 12 to 18 months with no further action.

The most immediate and visible manifestation of this crisis occurred last week, when a surge in nightly ETL data volumes caused the SQL Server to crash completely, taking the entire platform offline for several hours. Over 8,000 medical facilities lost access to patient metrics, compliance dashboards, bed availability data, and admit/discharge records — a disruption with direct clinical and regulatory consequences. This was not an isolated incident but the predictable outcome of a system that has already been pushed to its limits through hardware upgrades, index optimisation, and configuration tweaks, none of which have produced meaningful performance improvements.

Beyond the crash, the architecture has five interconnected structural failures. First, the system is a single point of failure: one SQL Server node hosts all critical data, and any hardware fault produces a total outage. Second, ETL processing is nightly-only, meaning facilities and customers receive data that is already up to 24 hours stale — incompatible with the real-time analytics the CTO wants to build. Third, the ETL pipeline relies on more than 70 custom-built SSIS packages, each hand-crafted for a specific data source type, creating an unmaintainable, fragile web of scripts that breaks with any schema change and cannot be extended without custom development work. Fourth, the analytics and reporting workflow requires exporting data nightly from SQL Server to separate analytical servers — creating data duplication, version sprawl, and departmental data silos that prevent cross-team analysis and waste significant storage. Fifth, the SQL Server architecture provides no pathway to machine learning or advanced analytics: the CTO's goal of building predictive patient models cannot be realised without a platform that allows ML frameworks to run directly against the data without extraction.

The sum of these failures is a platform that cannot scale, cannot recover quickly, cannot deliver real-time insights, and cannot support the innovation pipeline the business requires to maintain

its competitive position in the healthcare analytics market. A fundamental architectural change is not optional — it is urgent.

Failure Category	Current State	Business Impact
Single Point of Failure	One SQL Server node holds all data	Total outage on any hardware failure
Storage Saturation	12 TB disk at 70% — ~8.4 TB used	Full saturation in 12–18 months at 20% YoY growth
Nightly-Only ETL	70+ SSIS packages run batch nightly	Data up to 24 hours stale; no real-time capability
Data Silos	Nightly exports to analytical servers	Duplication, version sprawl, cross-team blindness
No Fault Tolerance	No rapid backup or recovery plan	Hours-to-days RTO on SQL Server restore
No ML Capability	Data must be extracted before modelling	CTO's ML roadmap cannot be executed

2. DATASET

The dataset processed by Medical Data Processing Company is large-scale, heterogeneous, high-velocity, and clinically sensitive — characteristics that make it uniquely challenging to manage in a traditional relational database environment and well-suited to a distributed Data Lake architecture. Understanding the dataset in depth is essential for appreciating why the current SQL Server infrastructure is inadequate and why the proposed Data Lake solution is the right fit.

2.1 Data Sources and Volume

Data originates from over 8,000 individual medical care facilities across the United States, spanning a wide spectrum of healthcare settings: hospitals, urgent care clinics, emergency rooms, nursing homes, and critical care units. Each facility transmits data to the platform using one of three mechanisms: pushing files to a company-hosted FTP server, exposing data through a REST API that the platform polls, or pushing data through a customer-hosted FTP server. All incoming files are compressed using gzip format and password-protected, meaning every record must be decompressed and validated before it can enter the processing pipeline.

2.2 Data Characteristics

77,000	15 M	3,500	700 K	20–300
Zip Files / Day	Data Files / Day	Zip Files / Hour	Data Files / Hour	XML Files per Zip

The dataset arrives in three primary formats — CSV (comma-separated values), TXT (pipe- or tab-delimited flat files), and XML (structured clinical records). Ninety-nine percent of incoming zip files range from 20 KB to 1.5 MB, with edge cases reaching up to 40 MB. XML zip archives are particularly complex: each can contain between 20 and 300 individual XML files, with each XML file representing a single patient or clinical record. This structure creates a wide variance in file-to-record ratios and adds significant processing complexity compared to flat file formats.

The data itself is clinically rich and operationally critical. It includes patient health metrics such as vital signs, lab results, and medication records; admission and discharge records with timestamps

and bed assignment data; compliance data required for regulatory reporting to CMS and state health agencies; and facility operational data including staffing levels and equipment usage. Because this data may contain Protected Health Information (PHI) and Personally Identifiable Information (PII), all storage, processing, and access must comply with the Health Insurance Portability and Accountability Act (HIPAA), including minimum-necessary access controls, AES-256 encryption at rest, TLS encryption in transit, and a minimum six-year retention period for medical records.

2.3 Growth Trajectory

The dataset is growing at 15–20% annually — a rate that will double the data volume approximately every four to five years. This growth is driven by two forces: the onboarding of new medical facilities (the company's primary growth vector) and the expansion of data types captured per facility as clinical data standards evolve. The following projections illustrate the storage trajectory with and without Parquet compression:

Year	Raw Data Size	Parquet (60% compression)	HDFS Raw (RF=3)	Nodes Required
0 (now)	8.0 TB	3.2 TB	24.0 TB	2 nodes
1	9.6 TB	3.8 TB	28.8 TB	3 nodes
2	11.5 TB	4.6 TB	34.5 TB	3 nodes
3	13.8 TB	5.5 TB	41.4 TB	4 nodes
5	20.0 TB	8.0 TB	60.0 TB	5 nodes

The contrast between the current SQL Server's 12 TB ceiling and the projected data growth makes clear that without architectural change the company will face storage exhaustion within two years. A distributed file system with horizontal scaling capability is not merely desirable — it is operationally mandatory.

3. SOLUTION STATEMENT

The proposed solution is a fully open-source, on-premise Enterprise Data Lake built on the Apache Hadoop ecosystem — replacing the fragile SQL Server monolith with a horizontally scalable, fault-tolerant, HIPAA-compliant data platform engineered to handle the company's current scale and grow sustainably for the next decade.

The solution is built around five guiding design principles that directly address each identified failure. The first principle is open-source first: every component is drawn from the Apache Software Foundation ecosystem — including Apache Hadoop, Spark, Kafka, NiFi, Hive, Atlas, and Ranger — ensuring zero vendor licensing fees, full operational freedom, and no proprietary lock-in. The second principle is separation of storage and compute: the Hadoop Distributed File System (HDFS) handles storage independently of Apache Spark and YARN which handle computation, allowing each to scale independently. When data volume grows, only storage nodes need to be added; when query load increases, only compute nodes need to be provisioned. The third principle is metadata-driven design: rather than maintaining 70+ custom SSIS scripts, a single parameterised PySpark framework reads transformation rules from Apache Atlas and the Hive Metastore, applying the correct processing logic to any data source type dynamically. New facilities onboard in hours rather than weeks. The fourth principle is fault tolerance and high availability: HDFS replicates every data block across three nodes, ZooKeeper provides automatic NameNode failover, Kafka replicates message partitions, and YARN reschedules failed tasks automatically — reducing recovery time from hours to seconds. The fifth principle is schema-on-read and data immutability: raw data is stored in its original form and never deleted, providing a permanent, auditable record required for HIPAA compliance and enabling time-travel queries through Apache Hudi.

The solution directly maps to every business and technical requirement. Near-real-time ingestion replaces nightly-only batch ETL. The single-node SQL Server is replaced by a multi-node distributed cluster with no single point of failure. The 70+ SSIS scripts are replaced by one framework. Data exports to analytical servers are eliminated — ML models and dashboards query the Data Lake directly. HIPAA compliance is achieved through Apache Ranger RBAC, AES-256 encryption, Kerberos authentication, and Apache Knox as a perimeter gateway. Hot/warm/cold/archive storage tiering reduces infrastructure costs by 40–60% compared to uniform SSD storage while maintaining full data accessibility.

Beyond stabilisation, the solution creates new competitive capabilities. Machine learning models built with Spark MLlib and TensorFlow can be trained and served directly on the Data Lake without data movement or extraction. Apache Superset, Grafana, and integrations with PowerBI and Tableau provide real-time and near-real-time dashboards. Presto and Trino enable federated ad-hoc SQL queries across all HDFS zones, legacy databases, and future data sources through a single interface — permanently eliminating the data silos that fragment the company's analytical capability today. This is not a tactical patch: it is a strategic architectural transformation that positions Medical Data Processing Company to serve its 8,000 facilities with the reliability, speed, and intelligence they require.

4. ARCHITECTURE

The proposed Data Lake follows a four-layer medallion architecture — Ingestion, Storage, Processing, and Serving — with a cross-cutting layer governing security, high availability, and monitoring across all layers. Each layer is independently scalable and composed entirely of open-source components from the Apache Software Foundation ecosystem. The architecture is deployed on-premise to satisfy the company's vendor lock-in avoidance requirement.

4.1 Ingestion Layer

The Ingestion Layer is the entry point for all data flowing into the Data Lake. Its primary responsibility is to reliably collect, decompress, validate, and route the 77,000 daily zip files and 15 million data records arriving from 8,000 facilities, while handling the 15–20% annual growth in throughput without architectural changes.

Apache NiFi serves as the primary orchestration engine. NiFi provides a visual, drag-and-drop dataflow management interface with over 300 built-in processors, including native FTP/SFTP polling, gzip decompression, file format routing, schema validation, and backpressure management. Backpressure is particularly critical: it is the exact mechanism that would have prevented last week's SQL Server crash by throttling upstream data ingestion when the downstream system is under stress. NiFi operates as a cluster with a baseline of three nodes, scaling to six nodes by Year 3 as throughput grows.

Apache Kafka serves as the high-throughput distributed message queue between NiFi and the downstream storage and processing layers. Each data format and facility type maps to a Kafka topic, initially provisioned with 12 partitions. Partitions can be expanded online without downtime as throughput grows. Kafka retains messages for configurable periods, enabling replay of any failed processing without data loss — a capability entirely absent from the current architecture. Apache Debezium, running as a Kafka Connect plugin, captures row-level changes from the legacy SQL Server database in real time by reading its transaction log — providing Change Data Capture (CDC) capability without modifying the source application. Apache Sqoop handles the initial bulk migration of the existing 8 TB from SQL Server to HDFS using parallel import jobs. Apache Flume collects log and file-based data from agent deployments at facility endpoints.

Ingestion Scaling Projections

Component	Baseline	Year 2	Year 3	Scaling Mechanism
Apache NiFi	3 nodes	4 nodes	6 nodes	Add nodes; auto-rebalance flows
Apache Kafka	12 partitions	18 partitions	24 partitions	Online partition expansion
Apache Sqoop	8 mappers	16 mappers	32 mappers	Increase -m flag; no infra change
Flume Agents	Per-endpoint	Per-endpoint	Per-endpoint	New agent per new facility

4.2 Storage Layer — HDFS Medallion Architecture

The Storage Layer is built on the Hadoop Distributed File System (HDFS), which distributes data across commodity servers with a replication factor of three — meaning three independent copies of every data block exist simultaneously. This single design choice eliminates the single-point-of-failure risk that caused last week's outage. HDFS supports petabyte-scale storage and horizontal scaling: adding a new node to the cluster causes HDFS to automatically rebalance data blocks with no downtime. Apache Parquet is used as the primary columnar file format, providing 60–80% compression versus raw CSV/XML and enabling analytical queries to read only the columns they need, dramatically reducing I/O and query latency.

Data progresses through four storage zones forming the medallion architecture:

Zone	Purpose	Technology	Key Properties	Retention
Raw Zone	Immutable landing area	HDFS + Parquet/ORC	Schema-on-read; write-once; never deleted	Permanent
Staging Zone	Cleaned & validated	HDFS + Apache Hudi	Dedup; CDC UPSERT; time-travel queries	Rolling 2 years
Curated Zone	Business-ready analytics	HDFS + Parquet (partitioned)	Aggregated; joined; patient KPIs	5+ years
Archive Zone	Cold long-term storage	HDFS cold tier / JBOD	Auto-tiered; 40–60% cost reduction	10+ years

Apache Hudi (Hadoop Upserts Deletes and Incrementals) is implemented in the Staging Zone to provide CDC and UPSERT support — a mandatory technical requirement. Hudi maintains a transaction log that supports time-travel queries, enabling compliance audits to reconstruct the exact state of patient records at any historical point. Apache Atlas provides the metadata management layer, registering every dataset across all zones with eleven concrete metadata attributes: source system, file format and schema version, load timestamp, processing status, row count, partition keys, PHI/PII classification flags, data owner, lineage graph, data quality score, retention policy, and transformation rules. Apache Ranger uses the PHI/PII classification flags from Atlas to enforce column-level access controls, ensuring only authorised personnel can access sensitive patient data.

Hot / Warm / Cold / Archive Tiering Strategy

Tier	Data Age	Storage Hardware	Query Latency	Estimated Cost vs Hot
Hot	0–6 months	SSD-backed HDFS nodes	Seconds	Baseline (high)
Warm	6–24 months	HDD HDFS data nodes	Minutes	~40% of hot
Cold	2+ years	JBOD high-density HDD HDFS	Hours	~20% of hot
Archive	7+ years (HIPAA)	Tape / Remote HDFS cluster	Days	~5% of hot

4.3 Processing Layer

The Processing Layer transforms raw and staged data into business-ready insights. Apache Spark, running on YARN as the cluster resource manager, serves as the unified batch and stream processing engine. Spark's in-memory computation provides 10–100× performance improvements over traditional disk-based processing and natively integrates with the Python data science ecosystem via PySpark.

For batch processing, a single metadata-driven PySpark framework reads transformation rules from Apache Atlas and applies cleansing, deduplication, schema validation, and aggregation to any data source type — replacing all 70+ legacy SSIS packages with one maintainable codebase. Apache Airflow orchestrates batch pipeline scheduling through Python-defined DAGs with built-in dependency management, retry logic, and a monitoring UI. For stream processing, Kafka Streams

handles lightweight stateful real-time processing, Apache Flink handles complex event processing requiring exactly once semantics, and Spark Structured Streaming provides sub-minute micro-batch latency for near-real-time dashboards.

Ad-hoc querying is served by three complementary SQL engines: Apache Hive for complex large-scan batch queries across all HDFS data; Apache Impala for sub-second interactive queries against the Curated Zone, powering real-time dashboards; and Presto/Trino for federated SQL across HDFS, the legacy SQL Server, and any future data sources simultaneously. For machine learning, Spark MLlib and TensorFlow on YARN train models directly against HDFS data without requiring data extraction — directly enabling the CTO's roadmap for patient risk scoring, readmission prediction, and anomaly detection. MLflow manages model versioning, experiment tracking, and REST-based model serving.

4.4 Serving Layer

The Serving Layer is the consumer-facing surface of the Data Lake, delivering curated data products to end users, customer applications, and automated systems. It serves five distinct use cases: compliance and operational SQL reports delivered through Apache Hive and Impala on a daily, weekly, and nightly schedule; real-time patient and facility dashboards through Apache Superset (open-source BI) with optional PowerBI and Tableau connectivity via ODBC/JDBC; a FastAPI-based REST microservice layer serving customer portal and mobile application requests; machine learning model serving through MLflow REST endpoints delivering patient risk scores and predictive analytics on demand; and ad-hoc federated analytics through Presto/Trino and Jupyter Notebooks enabling data analysts to explore across all zones without data movement.

4.5 Cross-Cutting: Security, HA, and Monitoring

Control	Tool	Coverage
Authentication	Kerberos	All cluster services and users
Authorisation (RBAC)	Apache Ranger	Row and column-level policies; HIPAA minimum-necessary
Encryption at Rest	HDFS TDE (AES-256)	All zones containing PHI/PII data
Encryption in Transit	TLS / SSL	NiFi, Kafka, HDFS, Spark — all data movement
Perimeter Gateway	Apache Knox	External API access to Hadoop cluster

Control	Tool	Coverage
Data Classification	Apache Atlas	PHI/PII tagging on every column and dataset
HA Failover	ZooKeeper	Automatic NameNode leader election and failover
Backup & Replication	Apache DistCp	Cross-cluster nightly replication to secondary HDFS
Cluster Monitoring	Prometheus + Grafana	Metrics, alerting, infrastructure dashboards
Log Management	ELK Stack	Centralised log aggregation and analysis

5. CONCLUSION

Medical Data Processing Company stands at a critical inflection point. The crash of its SQL Server during last week's ETL surge was not a one-off incident — it was the predictable, inevitable consequence of running a single-node, nightly-batch, proprietary database at the limits of its physical and architectural capacity. Without a fundamental change in platform, the company will face storage exhaustion within 18 months, increasing frequency and severity of outages, an inability to deliver the real-time analytics its customers require, and no viable pathway to the machine learning capabilities its CTO has set as a strategic priority.

The open-source Data Lake architecture proposed in this report directly resolves every identified failure. Replacing SQL Server with HDFS at a replication factor of three eliminates the single point of failure and reduces recovery time from hours to seconds. Replacing nightly-only ETL with Apache NiFi and Kafka brings near-real-time ingestion capability, converting stale data products into live, actionable intelligence. Replacing 70+ fragile SSIS packages with a single metadata-driven PySpark framework eliminates a major source of operational risk and dramatically reduces the time required to onboard new facility data sources. Replacing nightly data exports with a unified Data Lake enables all analytical workloads — dashboards, reports, and ML models — to query a single governed source of truth without data movement, duplication, or silos.

The proposed solution is not just technically sound — it is strategically aligned. Every tool selected is open-source, satisfying the business's explicit requirement to avoid vendor lock-in. The hot/warm/cold tiering strategy manages storage costs sustainably as data grows, with Parquet compression delivering 60–80% storage reduction and tiering policies reducing cold-storage cost-per-terabyte by 60–70%. Apache Ranger and HDFS Transparent Data Encryption ensure the platform meets HIPAA requirements for access control, encryption, and audit trail integrity, with the Raw Zone's write-once immutability providing the six-year medical record retention the law mandates.

The recommended next steps are: forming a cross-functional project steering committee within 30 days; conducting a detailed infrastructure capacity assessment to confirm data centre readiness for a minimum ten-node Hadoop cluster; developing a phased migration plan beginning with a parallel-run pilot covering 10% of facilities to validate the architecture before full cutover; engaging a certified Hadoop ecosystem implementation partner to support production deployment; and investing in training and hiring to build internal PySpark, Kafka, and Hadoop

operational expertise. With a committed implementation roadmap, the company can expect to have a production Data Lake operational within 12 to 18 months — transforming a liability into a lasting competitive advantage.

6. VALUE STATEMENT

The Data Lake modernisation delivers measurable, compounding value across five dimensions: operational reliability, cost efficiency, analytical capability, regulatory compliance, and competitive positioning. These values are not projections drawn from generic benchmarks — they are derived directly from the specific operational parameters of Medical Data Processing Company and calibrated to its data volumes, growth rate, and business model.

6.1 Operational Reliability

HDFS with a replication factor of three means that the loss of any single data node — regardless of cause — triggers automatic block rebalancing with zero data loss and zero downtime. ZooKeeper-managed NameNode High Availability ensures that even the loss of the cluster's primary metadata server triggers an automatic failover to a standby in under one minute. This transforms the recovery time objective from the current hours-to-days (full SQL Server restore from nightly backup) to sub-minute automatic failover. For 8,000 medical facilities depending on the platform for patient safety data, this improvement in reliability is not simply operational excellence — it is a clinical and regulatory imperative.

6.2 Cost Efficiency

Apache Parquet's columnar compression reduces raw data storage by 60–80% compared to the CSV and XML files currently loaded into SQL Server. This alone extends the effective storage runway from 18 months to five or more years before additional nodes are required. The hot/warm/cold tiering policy further reduces costs by automatically migrating data older than six months from high-cost SSD-backed nodes to lower-cost HDD nodes, and data older than two years to JBOD high-density storage — achieving a projected 40–60% reduction in total storage infrastructure cost compared to uniform SSD storage. The elimination of proprietary SQL Server licensing removes an ongoing cost centre. The replacement of 70+ custom SSIS scripts with a single PySpark framework dramatically reduces engineering maintenance hours, freeing the team to focus on new capabilities rather than firefighting broken ETL jobs.

6.3 Analytical Capability

The Data Lake enables four categories of analytical capability that are entirely impossible in the current architecture. Near-real-time dashboards — powered by Kafka Streams, Apache Flink, and Apache Impala — replace the nightly-refresh cycle with updates measured in seconds to minutes, giving facility operators live visibility into bed availability, patient metrics, and compliance status. Federated ad-hoc SQL through Presto/Trino eliminates data silos by allowing analysts to query across all HDFS zones, the legacy database, and future data sources through a single SQL interface without moving data. Machine learning at scale — using Spark MLlib and TensorFlow on YARN — allows data scientists to train patient risk models, readmission predictors, and anomaly detectors directly against the Data Lake with no extraction step. And end-to-end data lineage through Apache Atlas gives every stakeholder full visibility into where data came from, how it was transformed, and who has accessed it — a capability essential for both debugging and compliance auditing.

6.4 Compliance and Risk Reduction

HIPAA compliance is built into the architecture rather than retrofitted. AES-256 encryption at rest via HDFS Transparent Data Encryption and TLS in transit protect all PHI during storage and movement. Apache Ranger enforces row- and column-level access controls aligned with the HIPAA minimum-necessary principle, ensuring that no user or application can access data beyond their authorised scope. The Raw Zone's write-once, never-delete policy satisfies the HIPAA six-year medical record retention requirement with a cryptographically verifiable audit trail. Apache Atlas's PHI/PII column classification ensures that sensitive fields are automatically identified, tagged, and governed regardless of which zone they appear in — closing the compliance gaps that manual governance processes inevitably leave open.

6.5 Competitive Positioning

Medical Data Processing Company operates in a healthcare analytics market where the ability to deliver real-time, ML-powered insights is rapidly becoming table stakes. Competitors are already deploying predictive patient monitoring, automated compliance alerting, and AI-assisted clinical decision support. The proposed Data Lake architecture provides the technical foundation to compete on these capabilities — not by purchasing proprietary platforms, but by building a flexible, open-source platform that the company owns and controls entirely. The metadata-driven design means that as data science techniques evolve and new analytical frameworks emerge, the platform can adopt them without re-engineering the underlying data infrastructure. This creates a long-term compounding advantage: each new analytical capability deployed on the Data Lake increases the value of the platform and deepens the company's relationships with its 8,000 facility customers.
